Hydrochloric Acid Infusion for the Treatment of Metabolic Alkalosis in Surgical Intensive Care Unit Patients

Abstract

Background: Older reports of use of hydrochloric acid (HCl) infusions for treatment of metabolic alkalosis document variable dosing strategies and risk. **Objectives:** This study sought to characterize use of HCl infusions in surgical intensive care unit patients for the treatment of metabolic alkalosis. **Methods:** This retrospective review included patients who received a HCl infusion for >8 hours. The primary end point was to evaluate the utility of common acid-base equations for predicting HCl dose requirements. Secondary end points evaluated adverse effects, efficacy, duration of therapy, and total HCl dose needed to correct metabolic alkalosis. Data on demographics, potential causes of metabolic alkalosis, fluid volume, and duration of diuretics as well as laboratory data were collected. **Results:** A total of 30 patients were included, and the average HCl infusion rate was 10.5 ± 3.7 mEq/h for an average of 29 ± 14.6 hours. Metabolic alkalosis was primarily diuretic-induced ($n = 26$). Efficacy was characterized by reduction in the median total serum CO_2 from 34 to 27 mM/L ($P < 0.001$). The change in chloride ion deficit and change in apparent strong ion difference (SIDa) were not correlated with total HCl administered. There were no documented serious adverse effects related to HCl infusions. **Conclusion:** HCl was effective for treating metabolic alkalosis, and no serious adverse events were seen. In this clinical setting, the baseline chloride ion deficit and SIDa were not useful for prediction of total HCl dose requirement, and serial monitoring of response is recommended.

ABSTRACT**BACKGROUND**

Older reports of use of hydrochloric acid (HCl) infusions for treatment of metabolic alkalosis document variable dosing strategies and risk.

OBJECTIVES:

This study sought to characterize use of HCl infusions in surgical intensive care unit (SICU) patients for the treatment of metabolic alkalosis.

METHODS:

This retrospective review included patients who received a HCl infusion for > 8 hours. The primary endpoint was to evaluate the utility of common acid-base equations for predicting HCl dose requirements. Secondary endpoints evaluated adverse effects, efficacy, duration of therapy, and total HCl dose needed to correct metabolic alkalosis. Demographics, potential causes of metabolic alkalosis, fluid volume, duration of diuretics, and laboratory data were collected.

RESULTS:

Thirty patients were included, and the average HCl infusion rate was 10.5 ± 3.7 mEq/h for an average of 29 ± 14.6 hours. Metabolic alkalosis was primarily diuretic-induced ($n = 26$). Efficacy was characterized by reduction in the median total serum CO_2 from 34 to 27 mM/L ($p < 0.001$). The change in chloride ion deficit and change in apparent strong ion difference (SIDa) were not correlated with total HCl administered. There were no documented serious adverse effects related to HCl infusions.

CONCLUSION:

HCl was effective for treating metabolic alkalosis, and no serious adverse events were seen. In this clinical setting, the baseline chloride ion deficit and SID were not useful for prediction of total HCl dose requirement, and serial monitoring of response is recommended.

INTRODUCTION

The use of hydrochloric acid (HCl) for the treatment of metabolic alkalosis has been reported in the literature since the 1960's. The reported dosing strategies and risk of adverse effects varied. HCl infusions are typically used in severe or refractory metabolic alkalosis, and are rarely recommended as an initial treatment option. At the University of Rochester Medical Center (URMC), the use of HCl is primarily in the management of mild to moderate metabolic alkalosis, typically without alkalemia, secondary to use of continuous infusion of chloruretic, loop diuretics. At our institution, intravenous HCl is the treatment of choice for surgical intensive care unit (SICU) patients with diuretic-induced chloride depletion alkalosis that have poor or limited response to acetazolamide, that occurs in patients with concomitant renal failure, or is associated with a markedly elevated total serum CO₂(tCO₂) (e.g. >38mM/L).

HCl is not commercially available and must be extemporaneously compounded from concentrated, sterilized HCl solution. At our institution, the HCl is added to sterile water for injection in glass containers using Millex-FG 0.2micron hydrophobic filters (Merck Millipore Ltd, Cork, IRL), which are specifically designed for acids and are chemically safe, utilizing a Biohazard Safety Cabinet (Vertical Flow BSC) with appropriate Personal Protective Equipment. Dose requirements are typically based on the patient's base excess or chloride ion deficit. Typical concentrations are 0.1 or 0.2 N (100-200 mmol Cl⁻/L). Concentrations greater than 0.2 N have been associated with hemolysis, and are therefore not recommended.¹⁻⁴ Infusions of HCl have been well-tolerated when administered through the distal port of a central intravenous catheter¹⁻²⁰, with only rare reports of significant tissue necrosis emphasizing the need to confirm the proper placement of central catheters prior to infusion.²¹⁻²³ At our institution, HCl infusions are typically stopped based on clinical judgement and close monitoring of individual

response, (e.g., when the underlying cause of the metabolic alkalosis is removed or resolved and the acid-base disturbance is corrected). Ongoing monitoring includes CBC and electrolytes, blood gases, and vigilant observation of the infusion site and surrounding tissues.

The purpose of this retrospective study was to summarize and evaluate our experience with the use of intravenous HCl in SICU patients with a focus on evaluating the utility of common acid-base equations for predicting total HCl dose requirements. We also evaluated the effectiveness, safety, and indication for HCl therapy. This study was approved by and conducted in compliance with requirements of the University of Rochester Institutional Review Board, and informed consent was waived.

MATERIALS AND METHODS

A retrospective review of the medical record was completed for all patients who received greater than 8 hours of HCl infusion while admitted to the SICU service from January 1st, 2004 to December 31st, 2005. Patients were identified by querying the pharmacy records for the manufacturing and dispensing of HCl during the timeframe stated above.

Demographic information was collected including age (if greater than 90 years, we recorded >90), gender, height, weight, and race or ethnic group. Primary reason for ICU admission, and potential causes of and contributors to metabolic alkalosis were recorded. The total input and output of fluids during the ICU admission, as recorded on daily flow sheets, were calculated up to the point of the initiation of diuresis. The duration and dose of loop diuretics administered were collected along with total input and output of fluids during the exposure to diuretics. The volume of gastric secretions lost via nasogastric (NG) tube was recorded. Total blood products received from the time of admission until 24 hours after the conclusion of the HCl infusion were recorded. All available laboratory values were recorded starting at the

initiation of diuresis and continuing through 24 hours after the conclusion of the HCl infusion. These values include chemistries (sodium, chloride, creatinine, phosphate, corrected ionized calcium, albumin, potassium, total carbon dioxide, blood urea nitrogen, magnesium, lactate, and lactate dehydrogenase) and arterial blood gases (pH, pCO₂, pO₂, and bicarbonate). Hematologic parameters were also collected (hemoglobin, hematocrit, abnormal RBC morphology). The infusion rate, total dose and incremental doses of HCl were recorded. The incremental doses of HCl corresponded with the times of the serial laboratory values available for the patient. For each set of laboratory data that provided adequate data, chloride ion deficit and apparent strong ion difference (SIDa) were calculated. The following equations were used to calculate SIDa and chloride ion deficit:

$$\text{SIDa} = (\text{Na}^+ + \text{K}^+ + \text{Ca}^{2+} + \text{Mg}^{2+}) - (\text{Cl}^- + \text{lactate}^-)$$

$$\text{Chloride Ion Deficit} = (0.2 \text{ L/kg} \times \text{body weight (kg)}) \times ([\text{Cl}^-] \text{ Normal} - [\text{Cl}^-] \text{ Corrected})$$

$$[\text{Cl}^-] \text{ corrected} = [\text{Cl}^-] \text{ observed} \times ([\text{Na}^+] \text{ normal} / [\text{Na}^+] \text{ observed})$$

$$[\text{Cl}^-] \text{ Normal} = 103 \text{ mM/L}; [\text{Na}^+] \text{ Normal} = 140 \text{ mM/L}$$

Any adverse effects from the HCl infusion, as documented in the medical record, were recorded. In addition, any biochemical evidence of adverse events including moderate to severe metabolic acidosis (tCO₂ < 15 mM/L, or arterial pH < 7.25), or laboratory findings consistent with red blood cell hemolysis were recorded.

All data are reporting using appropriate descriptive statistics. Comparison of results before and after HCl infusion were completed using Wilcoxon signed ranks test. The relationship

between SIDa or chloride ion deficit and total HCl dose were evaluated using simple linear regression analysis. All analyses were considered descriptive and exploratory, and no sample size or power analysis were conducted.

RESULTS

The results of the pharmacy database query found records for 32 patients who had orders for HCl infusions. One patient never received the HCl infusion (unknown reason) and one patient failed to meet the inclusion criteria of >8 hours of total infusion time. Therefore, 30 patients were included in this study. Demographic information for the 30 patients is presented in Table 1.

The mean total milliequivalents (mEq) of HCl received, the total duration of the infusion, and average mEq/h for each patient is provided in Table 1. The average HCl infusion rate was 10.5 ± 3.7 mEq/h (4 to 16.6 mEq/h). The average duration of the HCl infusion was 29.0 ± 14.6 hours (9 to 68 hours).

The potential causes of metabolic alkalosis were evaluated for each patient who received a HCl infusion. Twenty-six patients were infused with HCl following sustained loop diuretic therapy, 3 patients following large blood product administration (>20 units of blood products received prior to HCl infusion), and 1 patient with an unknown mechanism for metabolic alkalosis (no loop diuretic administered, no significant NG losses, and no blood products received). Patients were primarily general surgery, vascular surgery, and liver transplant patients.

Figure 1 illustrates the change of total carbon dioxide (tCO₂) from pre- to post-HCl infusion which was characterized by a reduction in the median tCO₂ from 34 to 27 mM/L ($p < 0.001$).

The total HCl administered was not correlated with the change in chloride ion deficit. There was also no significant association between total HCl administered and change in SIDa.

There were no serious adverse effects documented in the medical record related to the HCl infusions. There were no documented cases of tissue necrosis or extravasation injuries. There were no cases of moderate to severe metabolic acidosis ($\text{pH} < 7.25$ or $\text{tCO}_2 < 15 \text{ mM/L}$) during or following the HCl infusion. Evaluation of CBC results including microscopy during the HCl infusions revealed no evidence of hemolysis.

DISCUSSION

Metabolic alkalosis is a common, if not relatively overlooked, finding in critically ill patients, and may present with concomitant metabolic acidosis. This acid-base disorder is classically described as being either “chloride responsive” or “chloride resistant”, with hypochloremic, hyperbicarbonatemic alkalosis (“chloride responsive”) being the predominant form seen in the ICU. This form of metabolic alkalosis is also referred to as chloride-depletion metabolic alkalosis (CDA). The most common underlying causes of CDA in the critically ill are loss of HCl from gastric secretions (vomiting or large volume NG aspiration of gastric contents) and the administration of chloruretic diuretics (urinary excretion of excess ammonium chloride). Other contributing factors may include delayed or incomplete recovery from hypercapnic acidosis, large volume blood transfusion, administration of alkali, and liver failure.²⁴⁻²⁶

The critically ill surgical patient often requires aggressive volume resuscitation in the early hours to days of their care in the ICU to maintain organ perfusion and decrease the risk of multiple organ failure. Once the patient is hemodynamically stable, off all vasopressor support, and no longer requiring volume resuscitation, relatively aggressive diuretic therapy is often initiated. The goals of this therapy include promoting the loss of excess extracellular fluid and shortening the time to extubation and transfer out of the ICU, thereby avoiding adverse sequelae associated with prolonged mechanical ventilation and extended ICU stays. At our site, diuresis is

most commonly achieved by administering a continuous infusion loop diuretic to maximize diuretic efficacy and efficiency and achieve the greatest overall net fluid loss. One of the most common complications that limit the extent of diuresis is the development of a “contraction alkalosis” with elevation of $t\text{CO}_2$ to >30 mM/L, without other clinical evidence of intravascular volume depletion. Effective treatment of this CDA will often allow continued diuresis.

Administration of sodium chloride in the form of crystalloid IV solutions would be an effective treatment for CDA but is counterproductive to removing the excess extracellular fluid and facilitating weaning from mechanical ventilation. Many ICU patients will not tolerate large doses of potassium chloride to reverse the chloride deficit. Ammonium chloride or arginine monochloride have been recommended in the past, but are often a poor choice in patients with underlying liver or renal disease and are no longer commercially available.

Alternative treatment options for ICU patients with diuretic-induced CDA include acetazolamide and hydrochloric acid.²⁴⁻³⁰ Acetazolamide has shown to be effective in reducing hyperbicarbonatemia in critically ill patients with mild to moderate metabolic alkalosis²⁷⁻³⁰, and is often used as a first-line agent for the treatment of diuretic-induced CDA. Typical practice at our institution is to administer at least 2 doses of acetazolamide (e.g., 500mg daily x 2 days) before consideration is given to starting an HCL infusion. In our experience, with continued administration of the loop diuretic infusion, acetazolamide has a moderate and short-lived effect on reducing $t\text{CO}_2$. It is relatively slow to work with nadir $t\text{CO}_2$ observed at 16-24 hours after the dose^{29,30}, and is relatively ineffective in the setting of significant renal insufficiency.

Advantages of HCl therapy include a direct correction of the underlying chloride deficiency, no need for end organ metabolism or elimination, titration of the infusion rate to a desired $t\text{CO}_2$, the ability to stop the treatment when goals are achieved, and the low cost of the

infusion. Disadvantages include the lack of a commercially available preparation, necessitating expertise and capabilities in manufacturing of sterile IV solutions, and the risk of serious extravasation injury.

Intravenous HCl is considered a treatment option for SICU patients at our institution with diuretic-induced CDA that have a poor or limited response to acetazolamide, concomitant renal failure, or a markedly elevated $t\text{CO}_2$ (e.g. >38 mM/L). The use of HCl infusions has been reported in the literature for more than 40 years, however most reports discuss its use in severe or refractory metabolic alkalosis^{1-20, 22} with only a few authors advocating it as a rational earlier treatment option^{3, 6, 18}. There are no reports in the literature describing the use of HCl infusion consistent with our application to reverse diuretic-induced CDA with the clinical intent of permitting continued diuresis of a patient without clinical evidence of intravascular volume depletion. This study was not of adequate design nor intended to evaluate the efficacy of HCl to permit continued diuresis or shorten time of mechanical ventilation, but was limited to evaluating the biochemical response to treatment.

Limitations of this study are consistent with it being a single-center, retrospective chart review, including the potential for missing or inadequately documented information in the medical record. A total of 30 patients were reviewed which therefore limited our ability to evaluate the relationship between laboratory parameters and total dose of HCl. In addition, many of the patients continued to receive chloruretic diuretics during the HCl infusion period which would limit the predictive value of baseline laboratory data for estimating the total HCl infusion dose needed to correct hyperbicarbonatemia. Not all patients had ideal laboratory parameters to calculate a pre-versus post-HCl infusion SIDa or chloride ion deficit since we had to use the data closest to the start and stop of the HCl infusion based upon routine clinical monitoring as

opposed to accurately timed samples relative to the infusion. In future prospective studies, a complete laboratory work up, including necessary values for SIDa and chloride ion deficit, immediately prior to initiation of HCl therapy, at frequent times during the infusion, and 12-24 hours following completion of the infusion is recommended. The lack of association between the chloride ion deficit and HCl dose is also likely related to other fluid losses and other potential sources of chloride.

There are reported cases in the literature of chest wall necrosis^{21, 23} with one fatal outcome²¹ following HCl infusion therapy. There was no documented clinical or laboratory evidence of safety issues with HCl therapy in our patient sample, however, given the small sample size, any conclusions about the overall safety of this therapy cannot be stated with confidence. To reduce the risk of extravasation and tissue injury, it is recommended that HCl only be infused using a central venous catheter, that the location of the catheter be confirmed radiographically prior to the start of the infusion, and that the HCl solution be infused using the most distal port of the catheter.

CONCLUSIONS

In this case series, HCl infusions were associated with a significant reduction in tCO₂ for SICU patients with predominantly diuretic-induced metabolic alkalosis, and no serious adverse events were observed. The total mEq of HCl received was not correlated with changes in SIDa or chloride ion deficit suggesting their limited predictive value. Therefore, routine and frequent monitoring of response and adjustment of the infusion rate are recommended for the safe use of HCl infusions. It is also strongly recommended that a firm policy be in place for the use of HCl including that it is only infused through the distal port of a properly placed central venous catheter.

ACKNOWLEDGEMENTS

We gratefully acknowledge Kelly Conn, PhD, MPH, Assistant Professor in the Department of Pharmacy Practice and Administration at St. John Fisher College in Rochester, NY, for her assistance with statistical analysis for this study.
